## **Business Cycles Facts**

---

# US real GDP per person

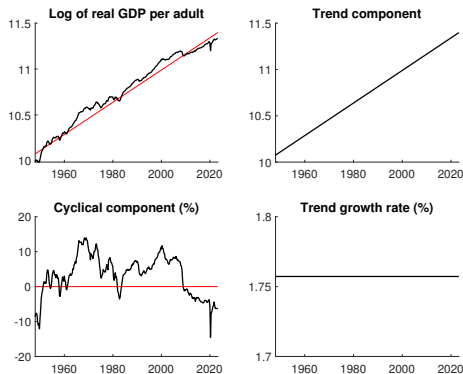

Real GDP per person grows thanks to technological progress (trend)

It fluctuates in the short term (recessions marked with grey bars)

How to separate cyclical component from the trend?

# Exponential trend

If the rate of technological progress is constant, real GDP **per adult** has exponential trend

We know now however that the rate of technological progress can change over time

Additionally, the cyclical component obtained that way can be positive during recessions and negative during booms – we need a more flexible approach

# Trend-cycle decomposition

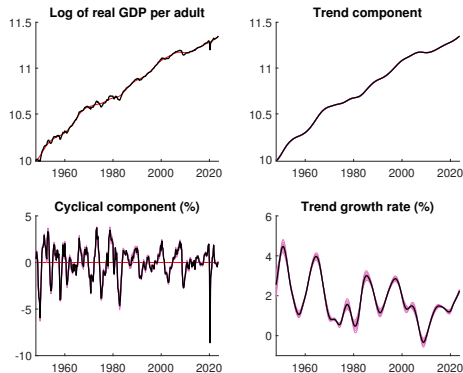

Let us assume the following structure: log of real GDP **per adult** has a trend component  $y^T$  and a cyclical component  $y^c$

The cyclical component is an AR(1) process with autoregression parameter  $\rho^c \in (0, 1)$

The trend component grows at a rate that follows a „smoothed” random walk

$$\begin{aligned}\ln y_t &= y_t^T + y_t^c \\ y_t^c &= \rho^c \cdot y_{t-1}^c + \epsilon_t^c \\ y_t^T &= y_{t-1}^T + x_t \\ x_t &= x_{t-1} + dx_t \\ dx_t &= dx_{t-1} + \epsilon_t^x\end{aligned}$$

# Trend-cycle decomposition

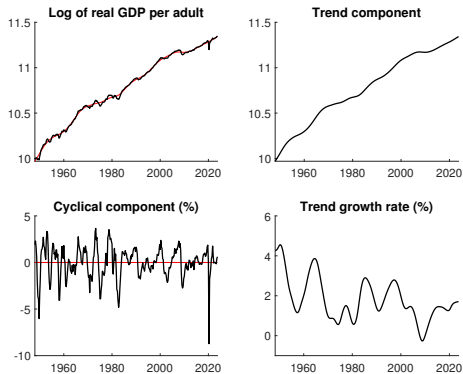

The trend growth rate of real GDP **per adult** fluctuates around 2% annually

We can clearly see periods of relatively higher growth: 1948-1972 and 1983-2006, and relative stagnation: 1973-1982 and 2007-currently

The cyclical component has sensible properties: it turns negative during recessions

# Hodrick-Prescott filter

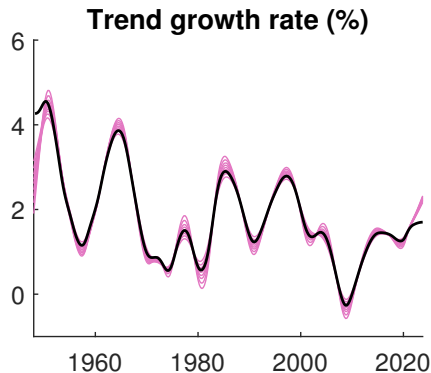

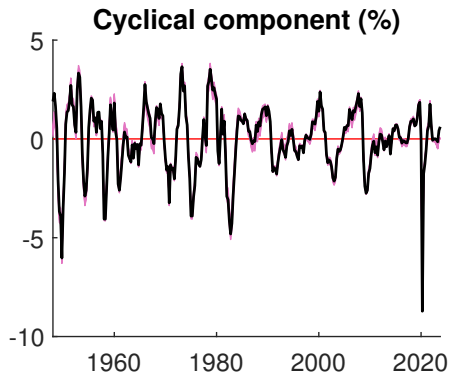

Similar results can be obtained using a purely statistical **Hodrick and Prescott (1980, 1997)** filter, with a „smoothing” parameter  $\lambda = 1600$  (typical value for quarterly data)

$$\min_{y_t^T} \left[ \sum (\ln y_t - y_t^T)^2 + \lambda \sum \left[ (y_{t+1}^T - y_t^T)^2 - (y_t^T - y_{t-1}^T)^2 \right] \right]$$

# Comparing trend-cycle decomposition and Hodrick-Prescott filter results

Statistically significant differences appear only near both ends of the sample

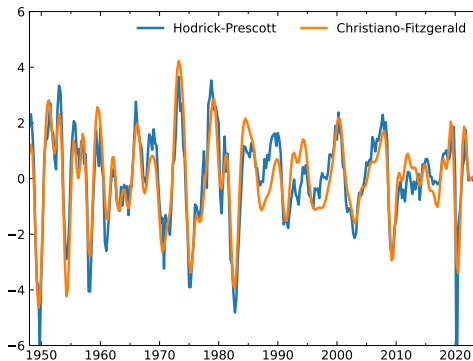

Typically we use „computationally cheap” statistical filters

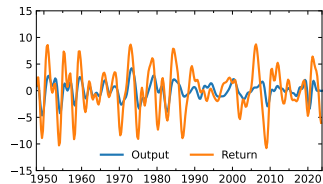

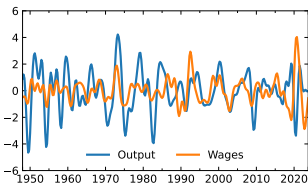

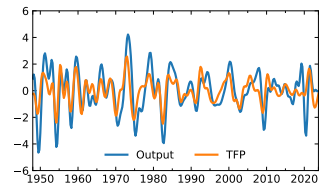

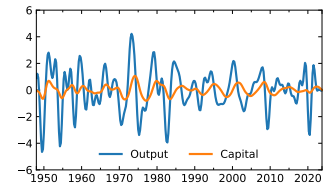

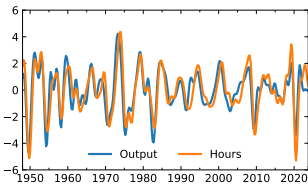

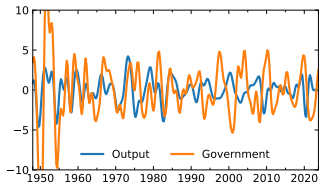

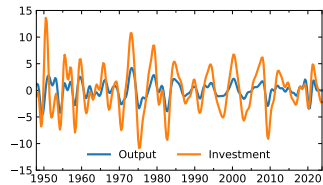

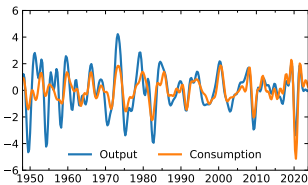

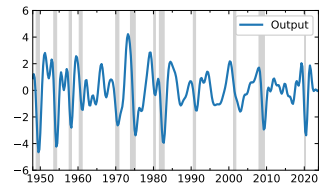

## Comparing Hodrick-Prescott and Christiano-Fitzgerald filter results

Christiano-Fitzgerald filter identifies similar cyclical components, but „smoother” (it discards volatility at short-term frequencies)

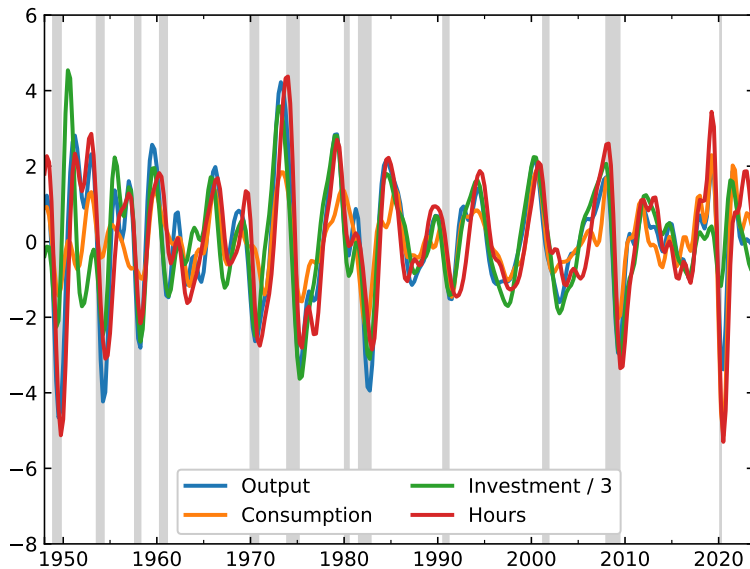

Due to visual niceness we will use Christiano-Fitzgerald filter for graphs, while quantitative results will be generated using Hodrick-Prescott filter

# Cyclical components of US macroeconomic variables

# Cyclical components of US macroeconomic variables

## Cyclical components of US macroeconomic variables

Selected statistical moments of cyclical components (1960Q1-2015Q4)

		Standard deviation	Correlation with $y$	Autocorrelation
Output (GDP)	$y$	1.47	1.00	0.87
Consumption	$c$	0.86	0.80	0.86
Investment	$i$	4.40	0.90	0.91
G + NX		2.74	0.11	0.52
Hours worked	$h$	1.52	0.78	0.91
Capital	$k$	0.45	0.34	0.97
Real hourly wages	$w$	0.90	0.27	0.78
Real return on capital	$r$	4.38	0.64	0.82
TFP	$z$	0.95	0.66	0.73

# Real Business Cycles

---

# „Modern” macroeconomics revolution

Growing dissatisfaction with the Keynesian paradigm in the seventies

## Lucas critique

- Keynesian models lack microfoundations and expectation formation
- If firms' and households' actions depend on their expectations about future policy, it is impossible to analyze the effects of this policy in a model that does not include expectations in an explicit form

How to model expectations?

- Adaptive: Fisher (1911), Cagan (1956), Friedman (1957)
- Rational: Muth (1961), Sargent and Wallace (1975), Lucas (1976)

Kydland and Prescott (1982): a very stylized macromodel with microfoundations and rational expectations performs surprisingly well in terms of its fit to the data

Sveriges Riksbank Prize in Economic Sciences in Memory of Alfred Nobel 2004 Laureate

Sveriges Riksbank Prize in Economic Sciences in Memory of Alfred Nobel 1995 Laureate

# Real Business Cycles Model (RBC)

Ramsey model with a neoclassical labor market and random „technology” shocks

To simplify notation assume constant population and stationary technology

Closed economy, no government (for now)

Perfect competition in goods and factors of production markets

Homogeneous final good with price normalized to 1 in every period,  
produced according to a neoclassical production function

All variables and prices expressed in real terms

Two groups of representative agents

- Households
- Firms

Households own factors of production directly

# Households

Maximize their **expected** utility, which depends negatively on hours worked  $h$

$$\begin{aligned} \max_{\{c_{t+j}, h_{t+j}, a_{t+j+1}\}_{j=0}^{\infty}} \quad & U_t = E_t \left[ \sum_{j=0}^{\infty} \beta^j \left( \frac{c_{t+j}^{1-\sigma}}{1-\sigma} - \psi \frac{h_{t+j}^{1+\varphi}}{1+\varphi} \right) \right] \\ \text{subject to} \quad & c_{t+j} + a_{t+j+1} = w_{t+j} h_{t+j} + (1 + r_{t+j}) a_{t+j} + d_{t+j} \end{aligned}$$

Parameter  $\varphi > 0$  is the inverse of Frisch elasticity of labor supply

Parameter  $\psi > 0$  is the labor disutility, chosen such that in the steady state  $h^* = 1$

Lagrangian

$$\mathcal{L} = \sum_{j=0}^{\infty} \beta^j E_t \left[ \frac{c_{t+j}^{1-\sigma}}{1-\sigma} - \psi \frac{h_{t+j}^{1+\varphi}}{1+\varphi} + \lambda_{t+j} [w_{t+j} h_{t+j} + (1 + r_{t+j}) a_{t+j} + d_{t+j} - c_{t+j} - a_{t+j+1}] \right]$$

# Households

„Expanded” Lagrangian for  $j = 0$  and  $j = 1$  (at decision time  $t$  variables from  $t$  are known)

$$\mathcal{L} = \frac{c_t^{1-\sigma}}{1-\sigma} - \psi \frac{h_t^{1+\varphi}}{1+\varphi} + \lambda_t [w_t h_t + (1+r_t) a_t + d_t - c_t - a_{t+1}] \\ + \beta E_t \left[ \frac{c_{t+1}^{1-\sigma}}{1-\sigma} - \psi \frac{h_{t+1}^{1+\varphi}}{1+\varphi} + \lambda_{t+1} [w_{t+1} h_{t+1} + (1+r_{t+1}) a_{t+1} + d_{t+1} - c_{t+1} - a_{t+2}] \right] + \dots$$

First Order Conditions (FOCs)

$$c_t : c_t^{-\sigma} - \lambda_t = 0 \quad \rightarrow \quad \lambda_t = c_t^{-\sigma}$$

$$h_t : -\psi h_t^\varphi + \lambda_t w_t = 0 \quad \rightarrow \quad \lambda_t = \psi h_t^\varphi / w_t$$

$$a_{t+1} : -\lambda_t + \beta E_t [\lambda_{t+1} (1+r_{t+1})] = 0 \quad \rightarrow \quad \lambda_t = \beta E_t [\lambda_{t+1} (1+r_{t+1})]$$

Euler equation and consumption-hours choice

$$c_t^{-\sigma} = \beta E_t [c_{t+1}^{-\sigma} (1+r_{t+1})]$$

$$c_t^{-\sigma} = \psi h_t^\varphi / w_t$$

Firms maximize their profits / dividends in every period,  
where  $z$  is a stochastic Total Factor Productivity (TFP)

$$\begin{aligned} \max_{y_t, k_t, h_t} \quad & d_t = y_t - w_t h_t - (r_t + \delta) k_t \\ \text{subject to} \quad & y_t = z_t \cdot k_t^\alpha h_t^{1-\alpha} \end{aligned}$$

Profit maximization problem

$$\max_{k_t, h_t} \quad d_t = z_t \cdot k_t^\alpha h_t^{1-\alpha} - w_t h_t - (r_t + \delta) k_t$$

First Order Conditions (FOCs)

$$k_t : \quad z_t \cdot \alpha k_t^{\alpha-1} h_t^{1-\alpha} - (r_t + \delta) = 0 \quad \rightarrow \quad r_t = z_t \cdot \alpha k_t^{\alpha-1} h_t^{1-\alpha} - \delta = \alpha \frac{y_t}{k_t} - \delta$$

$$h_t : \quad z_t \cdot (1 - \alpha) k_t^\alpha h_t^{-\alpha} - w_t = 0 \quad \rightarrow \quad w_t = z_t \cdot (1 - \alpha) k_t^\alpha h_t^{-\alpha} = (1 - \alpha) \frac{y_t}{h_t}$$

We can easily show that economic profits are equal to 0

# General equilibrium

The capital market is in equilibrium:  $a_t = k_t$  for all  $t$

Plug in the expression for profits into the household budget constraint to arrive at the economy's resource constraint

$$c_t + a_{t+1} = w_t h_t + (1 + r_t) a_t + d_t$$

$$c_t + k_{t+1} = w_t h_t + (1 + r_t) k_t + d_t$$

$$c_t + k_{t+1} = w_t h_t + (1 + r_t) k_t + y_t - (r_t + \delta) k_t - w_t h_t$$

$$c_t + k_{t+1} = y_t + (1 - \delta) k_t$$

It is convenient to explicitly define investment

$$i_t \equiv k_{t+1} - (1 - \delta) k_t \quad \rightarrow \quad y_t = c_t + i_t$$

# Stochastic Total Factor Productivity (TFP)

TFP evolves according to an AR(1) process in logs

$$\ln z_t = \rho_z \cdot \ln z_{t-1} + \epsilon_{z,t}$$

where  $\rho_z \in (0, 1)$  and  $\epsilon_{z,t} \sim \mathcal{N}(0, \sigma_z^2)$

In the absence of shocks (steady state)  $\ln z = 0$  and  $z = 1$

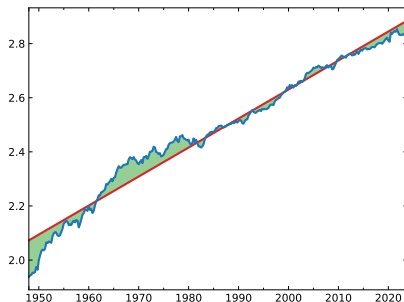

# Stochastic Total Factor Productivity (TFP)

How can we estimate  $z$  from the data? Using the Cobb-Douglas production function

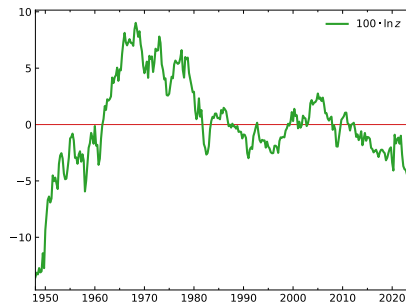

$$Y_t = K_t^\alpha (A_t \cdot L_t h_t)^{1-\alpha} \equiv z_t \left[ A_0 (1+g)^t \right]^{1-\alpha} K_t^\alpha (L_t h_t)^{1-\alpha}$$

$$\ln TFP_t = \ln Y_t - \alpha \ln K_t - (1-\alpha) \ln (L_t h_t)$$

$$\ln z_t = \ln TFP_t - (1-\alpha) (\ln A_0 + gt)$$

$$\ln z_t = \rho_z \cdot \ln z_{t-1} + \epsilon_{z,t}$$

$$\rho_z \approx 0.966, \sigma_z \approx 0.82$$

## Where can negative TFP shocks come from?

Expand production function with energy input  $E$ , where  $\chi \in (0, 1)$

$$\tilde{Y}_t = \left[ K_t^\alpha (A_t \cdot L_t h_t)^{1-\alpha} \right]^\chi E_t^{1-\chi} \equiv \tilde{A}_t \left[ K_t^\alpha (L_t h_t)^{1-\alpha} \right]^\chi E_t^{1-\chi} \equiv \tilde{A}_t X_t^\chi E_t^{1-\chi}$$

Assume  $E$  is fully imported at relative price  $p^E$ . The GDP is then given by

$$Y_t = \max_{E_t} \left\{ \tilde{A}_t X_t^\chi E_t^{1-\chi} - p_t^E E_t \right\}$$

$$E_t : \quad (1 - \chi) \tilde{A}_t X_t^\chi E_t^{-\chi} - p_t^E = 0 \quad \rightarrow \quad E_t = \left[ (1 - \chi) \tilde{A}_t / p_t^E \right]^{1/\chi} X_t$$

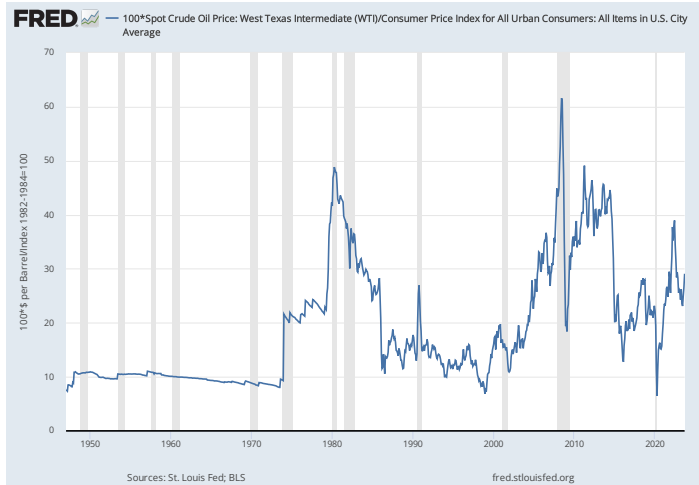

$$Y_t = \tilde{A}_t X_t^\chi \left[ \frac{(1 - \chi) \tilde{A}_t}{p_t^E} \right]^{(1-\chi)/\chi} X_t^{1-\chi} - p_t^E \left[ \frac{(1 - \chi) \tilde{A}_t}{p_t^E} \right]^{1/\chi} X_t$$

$$Y_t = \chi \tilde{A}_t^{1/\chi} \left( \frac{1 - \chi}{p_t^E} \right)^{(1-\chi)/\chi} X_t \equiv TFP_t \cdot X_t = TFP_t \cdot K_t^\alpha (L_t h_t)^{1-\alpha}$$

TFP depends then negatively on relative energy prices:  $\partial TFP_t / \partial p_t^E < 0$

# Relative spot price of oil barrel in the USA

# Full set of general equilibrium conditions

System of 8 equations and 8 unknowns:  $y, c, i, h, k, w, r, z$  (can be reduced to 4:  $c, h, k, z$ )

$$\text{Euler equation} : c_t^{-\sigma} = \beta E_t [c_{t+1}^{-\sigma} (1 + r_{t+1})] \quad (1)$$

$$\text{Consumption-hours choice} : c_t^{-\sigma} = \psi h_t^{\varphi} / w_t \quad (2)$$

$$\text{Production function} : y_t = z_t \cdot k_t^{\alpha} h_t^{1-\alpha} \quad (3)$$

$$\text{Real return on capital} : r_t = z_t \cdot \alpha k_t^{\alpha-1} h_t^{1-\alpha} - \delta \quad (4)$$

$$\text{Real hourly wage} : w_t = (1 - \alpha) y_t / h_t \quad (5)$$

$$\text{Investment} : i_t = k_{t+1} - (1 - \delta) k_t \quad (6)$$

$$\text{Output accounting} : y_t = c_t + i_t \quad (7)$$

$$\text{TFP AR(1) process} : \ln z_t = \rho_z \cdot \ln z_{t-1} + \epsilon_{z,t} \quad (8)$$

This time we cannot „move”  $c_{t+1}$  to the left hand side of the Euler equation

## Steady state: closed form solution

Recall that the RBC model is just an extension of the Ramsey model

We already know that  $z^* = 1$ . Next start with the Euler equation (1)

$$c^{-\sigma} = \beta c^{-\sigma} (1 + r) \quad \rightarrow \quad r = 1/\beta - 1 = \rho$$

Since  $h^* = 1$ , we can find the level of capital per worker from equation (4)

$$r = z \cdot \alpha k^{\alpha-1} h^{1-\alpha} - \delta \quad \rightarrow \quad k = \left( \frac{\alpha}{r + \delta} \right)^{1/(1-\alpha)} = \left( \frac{\alpha}{\rho + \delta} \right)^{1/(1-\alpha)}$$

Once  $k^*$  is found, we can easily get the steady state values of remaining variables

$$y = k^\alpha, \quad w = (1 - \alpha) y, \quad i = \delta k, \quad c = y - i = y - \delta k$$

Parameter  $\psi$  satisfies equation (2) under  $h^* = 1$

$$\psi \equiv w \cdot c^{-\sigma}$$

We consider now more variables, but the steady state is identical to Ramsey

## Transition dynamics: special case

Assume logarithmic utility  $\sigma = 1$  and full capital depreciation  $\delta = 1$

Again „guess-and-verify” that the model behaves like a Solow model

$$c_t = (1 - s) y_t \quad \text{and} \quad i_t = s y_t$$

Euler equation

$$\begin{aligned} c_t^{-1} &= \beta E_t [c_{t+1}^{-1} (1 + r_{t+1})] \\ \frac{1}{(1-s)y_t} &= \beta E_t \left[ \frac{1 + \alpha z_{t+1} k_{t+1}^{\alpha-1} h_{t+1}^{1-\alpha} - \delta}{(1-s) z_{t+1} k_{t+1}^{\alpha} h_{t+1}^{1-\alpha}} \right] \\ 1/y_t &= \beta E_t [\alpha/k_{t+1}] \\ k_{t+1} &= \alpha \beta y_t = \alpha \beta \cdot z_t k_t^{\alpha} h_t^{1-\alpha} = i_t \end{aligned}$$

Consumption and wages

$$c_t = (1 - \alpha \beta) y_t = (1 - \alpha \beta) z_t k_t^{\alpha} h_t^{1-\alpha} \quad \text{and} \quad w_t = (1 - \alpha) z_t k_t^{\alpha} h_t^{-\alpha}$$

Can show that hours worked are constant (and equal to 1 by normalization)

## Impulse response functions: special case

Output, consumption and investment depend positively on  $z$  (and also on  $k$ )

$$\ln z_t = \rho_z \ln z_{t-1} + \epsilon_{z,t}, \quad y_t = z_t k_t^\alpha, \quad i_t = k_{t+1} = \alpha\beta \cdot z_t k_t^\alpha, \quad c_t = (1 - \alpha\beta) z_t k_t^\alpha$$

TFP shocks send these three variables in the same direction

Focus on the dynamics of capital ( $\tilde{x}$  denotes % deviation from steady state)

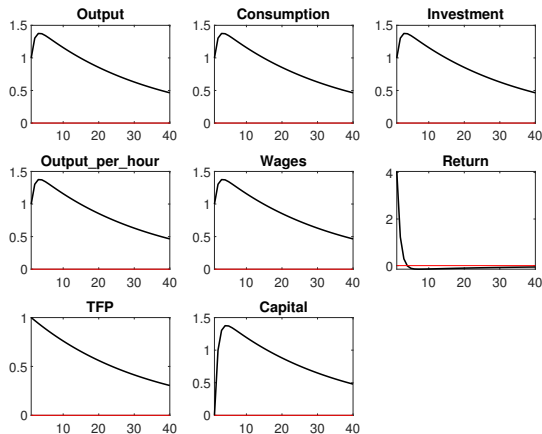

$$\begin{aligned} \ln k_{t+1} &= \ln \alpha\beta + \alpha \ln k_t + \ln z_t \quad \text{and} \quad \ln k^* = \ln \alpha\beta + \alpha \ln k^* \\ \ln k_{t+1} - \ln k^* &= \alpha (\ln k_t - \ln k^*) + \ln z_t \quad \rightarrow \quad \tilde{k}_{t+1} = \alpha \tilde{k}_t + \ln z_t \end{aligned}$$

The system (initially in the steady state) receives a shock  $\epsilon_z$  in period  $t$  (impulse)

$$\begin{aligned} \ln z_t &= \epsilon_z & \tilde{k}_{t+1} &= \alpha \tilde{k}_t + \ln z_t = \alpha \cdot 0 + \epsilon_z = \epsilon_z \\ \ln z_{t+j} &= (\rho_z)^j \epsilon_z & \tilde{k}_{t+j+1} &= \alpha \tilde{k}_{t+j} + \ln z_{t+j} = \alpha \tilde{k}_{t+j} + (\rho_z)^j \epsilon_z \end{aligned}$$

# Impulse response functions: special case

The economy receives a positive shock  $\epsilon_z$  whose influence dies out over time

Percent deviations from steady state values (for  $r$  percentage points)

## Transition dynamics: general case

As in the case of Ramsey model, the RBC model cannot be solved analytically

We can easily solve the model using numerical methods:

- Perturbation around the steady state (with approximation error, but „cheap“)
- Dynamic programming (global solution but computationally (too) heavy)

Usually we employ perturbation methods provided by **Dynare** software

How does it work for (log-)linear approximation?

We transform the system of forward-looking equations into a backward-looking vector autoregression (VAR) system

What magic allows this? We assume rational expectations (model-consistent)

Agents make forecast errors (e.g.  $\epsilon_z$  cannot be foreseen), but the forecasts are unbiased (they are correct on average)

We can also solve models under several non-rational expectation formation mechanisms

Parameter values can be chosen in at least two ways:

- Calibration: pick values according to data external to the model (e. g.  $\alpha \approx 1/3$ ) or such that the steady state levels correspond to long sample averages
- Estimation: econometric procedure picks „most probable” values given the properties of supplied time series

First I extend the basic model a bit by adding trend population and productivity growth

I also add public expenditures (summed with net exports)  
with two components: quasi-permanent and transitory

## Parameter values

Some parameters are set in line with long-term averages in the US

- Annual growth rate of adult (age 16 and over) population: 1.26%
- Annual growth rate of GDP per adult in the long run: 1.77%
- Investment to GDP ratio: 25.2%
- Public expenditures and net exports ratio to GDP: 19.7%
- Estimated capital to annual GDP ratio: 2.58 (10.3 times quarterly GDP)

Parameter	Value	Justification
$\alpha$	1/3	Capital share of income
$\sigma$	1	Logarithmic utility function (consumption)
$\kappa$	0.5	Logarithmic utility function (leisure)
$\delta$	0.0169	From capital accumulation equation (quarterly)
$\beta$	0.9922	From Euler equation (quarterly)
$\psi$	0.8913	Steady state hours worked = 1

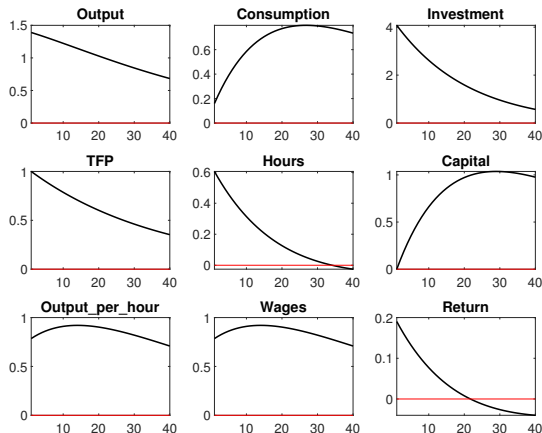

## Parameter values

Parameters governing stochastic processes are estimated (results)

Parameter	Value	Justification
$\rho_z$	0.9766	TFP shock persistence
$\rho_s$	0.6796	Quasi-permanent G+NX shock persistence
$\rho_f$	0.7437	Transitory G+NX shock persistence
$\sigma_z$	0.8226	TFP shock standard deviation
$\sigma_s$	0.1453	Quasi-permanent G+NX shock standard deviation
$\sigma_f$	0.5159	Transitory G+NX shock standard deviation

# Impulse response functions: TFP shock

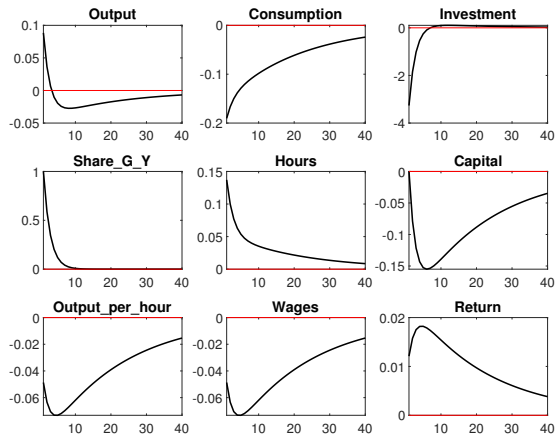

The economy receives a positive shock  $\epsilon_z$  whose influence dies out over time

Percent deviations from steady state values (for  $r$  percentage points)

# Impulse response functions: transitory G shock

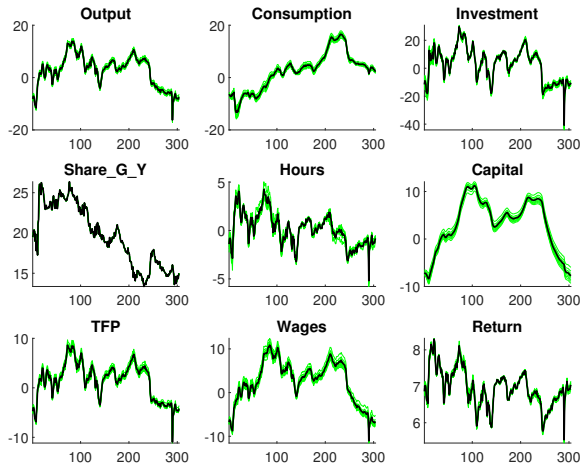

Transitory increase in public expenditures, financed via lump-sum tax

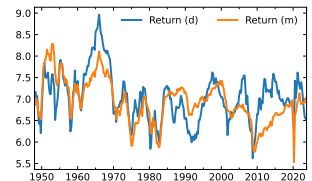

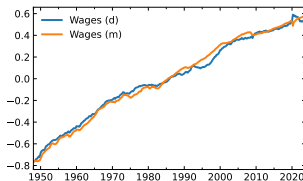

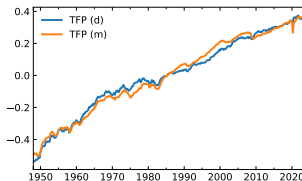

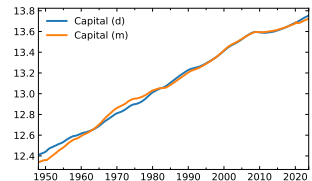

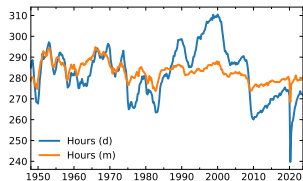

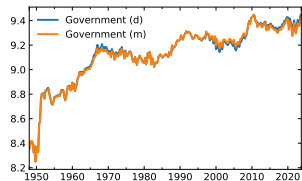

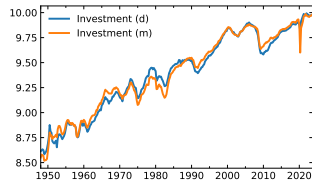

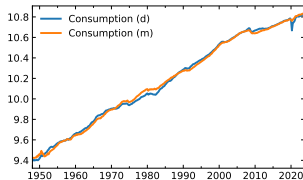

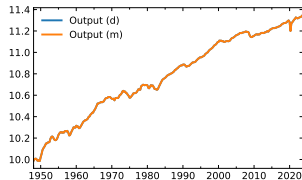

Percent deviations from steady state values (for  $r$  percentage points)

## Estimated deviations from steady state

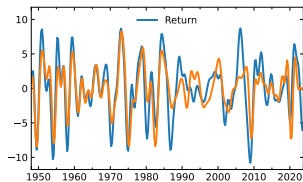

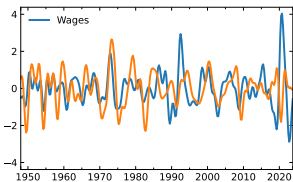

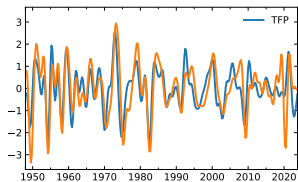

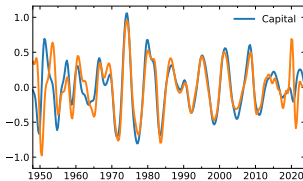

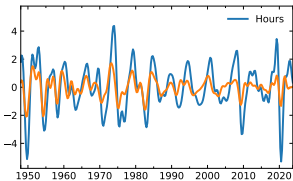

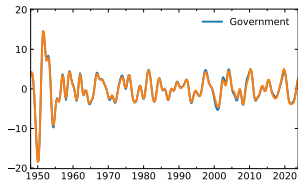

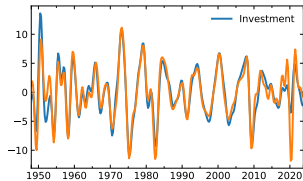

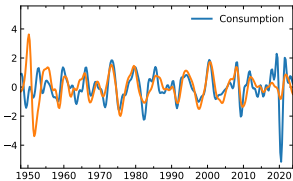

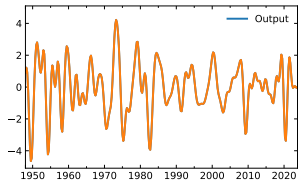

The model is only informed on the time series of quarterly real GDP per adult growth rates and share of public expenditure (+NX) to GDP. Deviations from the steady state:

# Model vs data comparison: levels

# Model vs data comparison: cyclical components

## Model vs data comparison: statistical moments (1960Q1-2015Q4)

		Std. dev.		Corr. with $y$		Autocorr.		Correlation
		Data	Model	Data	Model	Data	Model	Data-Model
Output	$y$	1.47	1.47	1.00	1.00	0.87	0.87	1.00
Consumption	$c$	0.86	0.83	0.80	0.73	0.86	0.94	0.79
Investment	$i$	4.40	4.41	0.90	0.96	0.91	0.89	0.95
Hours	$h$	<b>1.52</b>	<b>0.60</b>	0.79	0.97	0.91	0.82	0.66
Capital	$k$	0.45	0.43	0.34	0.28	0.97	0.96	0.96
Real wage	$w$	0.90	0.92	<b>0.27</b>	<b>0.99</b>	0.78	0.89	0.23
Return on $k$	$r$	4.38	3.29	0.65	0.95	0.82	0.86	0.77
TFP	$z$	0.95	1.04	<b>0.66</b>	<b>1.00</b>	0.82	0.87	0.67

Model performance is surprisingly good! There are some issues though:

- Hours worked are much more volatile in the data
- Real wages can be pro- or counter-cyclical, in the model they are always pro-cyclical
- TFP and output are correlated in the data, but not 100% correlated as in the model

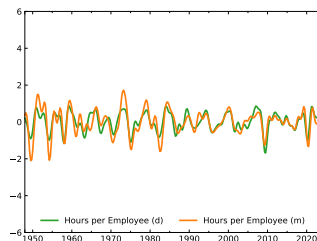

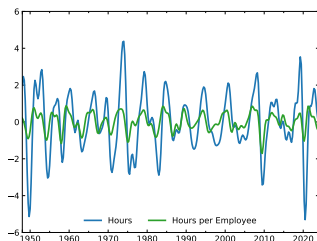

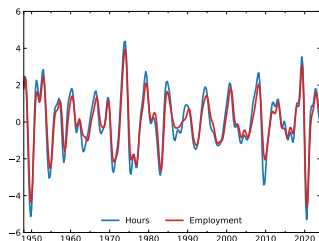

# Why the RBC model does not model labor market well?

The vast majority of hours worked volatility over the business cycle is due to employment-unemployment flows rather than changes in hours worked per employee

Volatility of hours per employee is relatively small (correlation with RBC is 0.81)

RBC model mistakenly attributes remaining volatility of total hours to TFP volatility

Another shortcoming of RBC is assumption that real wages are bargained over, where in reality we typically bargain over nominal wages, while the price level is an „independent” variable over which we form expectations

## What lies ahead

We can model both long-run growth and business cycles phenomena starting from the same model (Ramsey) – a huge surprise in the eighties!

Certainly we need to replace the neoclassical labor market block with a better mechanism, like a search and matching model

We also need to add the nominal side of the economy
